Abstract

Interoperation for Lazy and Eager Evaluation

by

William Faight

Programmers forgo existing solutions to problems in other programming languages where software interoperation proves too cumbersome; they remake solutions, rather than reuse them. To facilitate reuse, interoperation must resolve language incompatibilities transparently. To address part of this problem, we present a model of computation that resolves lazy and eager evaluation strategies using dual notions of evaluation contexts and values to mirror the lazy evaluation strategy in the eager one. This method could be extended to resolve incompatible evaluation contexts for expressions common to any pair of languages.

Acknowledgements

I thank my family and friends, especially my parents, Jerry and Jo Ann, for their encouragement, advice, and support, without which this would not have been possible.

Chapter 1

Introduction

Programmers forgo existing solutions to problems in other programming languages where software interoperation proves too cumbersome; they remake solutions, rather than reuse them. To facilitate reuse, interoperation must resolve language incompatibilities transparently. To address part of this problem, we present a model of computation that resolves lazy and eager evaluation strategies.

Matthews and Findler presented a method of safe interoperation between languages with incompatible polymorphic static and dynamic type systems [1]. We observe that their method is insufficient for safe interoperation between languages with incompatible lazy and eager evaluation strategies, then explain the underlying problem, and then finally present a method of interoperation that resolves this incompatibility.

The model of computation of Matthews and Findler comprises two eager languages based on ML and Scheme. We extend their model of computation with a third language that is based on Haskell and identical to their ML-like

```

sh {N} (cons (wrong N "Not a number") (nil N))      →
cons (sh N (wrong N "Not a number")) (sh {N} (nil N)) →
Error: "Not a number"

```

Figure 1.1: Scheme forces the conversion of list construction operands.

```

sh {N} (cons (wrong N "Not a number") (nil N))      →
cons (sh N (wrong N "Not a number")) (sh {N} (nil N)) →
cons (sh N (wrong N "Not a number")) (nil N)

```

Figure 1.2: Scheme does not force the conversion of list construction operands.

language, except it is lazy. We introduce lists to all three languages. Hereafter, we use the names of Haskell, ML, and Scheme to refer to their counterparts in our model of computation.

Unlike ML and Scheme, Haskell does not evaluate function arguments or list construction operands. These three evaluation contexts comprise the set of incompatible evaluation contexts between Haskell and ML, and Haskell and Scheme. Since Haskell permits unused erroneous or divergent expressions in these evaluation contexts and ML and Scheme do not, there are Haskell values that have no counterpart in ML and Scheme. Attempting to convert such values to ML and Scheme forces the evaluation of such expressions and breaks the transparency of interoperation.

Figure 1.1 demonstrates how a straightforward introduction of Haskell to the model of Matthews and Findler breaks the transparency of interoperation when converting a list construction from Haskell to Scheme. The Haskell list construction contains an erroneous operand that Scheme forces to evaluate in the process of converting the Haskell list construction. Figure 1.2 demonstrates Scheme correctly deferring the evaluation of the erroneous Haskell list construction operand

$$\begin{array}{ll}
(\text{hs } (\mathbb{N} \rightarrow \mathbb{N}) (\lambda x_S. \bar{0})) (\text{wrong } \mathbb{N} \text{ "Not a number"}) & \rightarrow \\
(\lambda x_H : \mathbb{N}. \text{hs } \mathbb{N} ((\lambda x_S. \bar{0}) (\text{sh } \mathbb{N} x_H))) (\text{wrong } \mathbb{N} \text{ "Not a number"}) & \rightarrow \\
\text{hs } \mathbb{N} ((\lambda x_S. \bar{0}) (\text{sh } \mathbb{N} (\text{wrong } \mathbb{N} \text{ "Not a number"}))) & \rightarrow \\
\text{Error: "Not a number"} &
\end{array}$$

Figure 1.3: Scheme forces the conversion of arguments.

$$\begin{array}{ll}
(\text{hs } (\mathbb{N} \rightarrow \mathbb{N}) (\lambda x_S. \bar{0})) (\text{wrong } \mathbb{N} \text{ "Not a number"}) & \rightarrow \\
(\lambda x_H : \mathbb{N}. \text{hs } \mathbb{N} ((\lambda x_S. \bar{0}) (\text{sh } \mathbb{N} x_H))) (\text{wrong } \mathbb{N} \text{ "Not a number"}) & \rightarrow \\
\text{hs } \mathbb{N} ((\lambda x_S. \bar{0}) (\text{sh } \mathbb{N} (\text{wrong } \mathbb{N} \text{ "Not a number"}))) & \rightarrow \\
\text{hs } \mathbb{N} \bar{0} & \rightarrow \\
\bar{0} &
\end{array}$$

Figure 1.4: Scheme does not force the conversion of arguments.

and producing as a result the counterpart Scheme list construction.

Moreover, since the conversion of functions from ML and Scheme to Haskell requires the application of the original function to the converted Haskell argument, ML and Scheme always force the evaluation of the converted Haskell argument, even if it is never used. The application of such converted functions effectively changes the order of evaluation of Haskell and breaks the transparency of inter-operation.

Likewise, figure 1.3 demonstrates the conversion of a function from Haskell to Scheme. Scheme forces the evaluation of the erroneous Haskell argument in the process of applying the Scheme function, even though the Haskell argument is never used. From the perspective of the outermost Haskell application, the argument must have been used, but it was not. Figure 1.4 demonstrates Scheme not forcing the evaluation of the Haskell argument, which allows the Scheme function to produce a number.

Chapter 2

Model of Computation

To preserve the transparency of interoperation, ML and Scheme must not force Haskell to evaluate reducible expressions in Haskell boundaries in the incompatible evaluation contexts, and force their evaluation in all other evaluation contexts. Haskell boundaries must be a new kind of value that ML and Scheme can force to become a reducible expression in certain evaluation contexts, and thereby force the evaluation of the inner Haskell reducible expressions to Haskell values and the conversion of those values to ML or Scheme.

Since ML and Scheme do not force Haskell to evaluate in some evaluation contexts, we must factor Haskell boundaries out of ML and Scheme evaluation context nonterminals, E , into new evaluation context nonterminals. We name these new nonterminals F because they allow ML and Scheme to force Haskell to evaluate, and we rename the primary evaluation context nonterminals from E to U (unforced) because they do not. Likewise, we factor Haskell boundaries out of ML and Scheme value nonterminals, v , into new value nonterminals. We name these new nonterminals f (forced) and rename the old value nonterminals from v to u (unforced). We rename Haskell evaluation contexts and values to F and

f , respectively.

In ML and Scheme, we tie F and U together by replacing U with F in the syntax and operational semantics in all evaluation contexts except the incompatible ones. Likewise, we tie f and u together by replacing u with f in the syntax and operational semantics in those same evaluation contexts. F evaluation contexts produce f values, and U evaluation contexts produce u values. U only applies to incompatible evaluation contexts, and F applies to all others. ML and Scheme use F to evaluate expressions. We rename the meta evaluation context from \mathcal{E} to \mathcal{F} .

Transparency is restored for interoperation in all cases with our changes to the model of computation of Matthews and Findler.

Theorem 1. *Interoperation is transparent:*

1. $e_H \equiv \mathbf{mh} \ t_M \ t_H \ e_H \equiv \mathbf{sh} \ t_H \ e_H$
2. $e_M \equiv \mathbf{hm} \ t_H \ t_M \ e_M \equiv \mathbf{sm} \ t_M \ e_M$
3. $e_S \equiv \mathbf{hs} \ t_H \ e_S \equiv \mathbf{ms} \ t_M \ e_S$

where \equiv denotes contextual equivalence.

Proof. By structural induction. □

Another complication with introducing Haskell to the model of computation is how to convert type abstractions between Haskell and ML. The application of a converted type abstraction cannot substitute the type argument into the nested expression because the type argument is meaningless in the nested expression's language. Instead, the application substitutes the type argument and a lump into

the boundary's outer and inner types, respectively. Since the natural embedding requires the boundary's outer and inner types to be equal [1], we use a new notion of equality called lump equality that allows lumps within the boundary's inner type to match any corresponding type in the boundary's outer type.

Legends of symbol and syntax names are presented in figures 2.1-2.3; Haskell is presented in figures 2.4-2.8; ML is presented in figures 2.9-2.13; Scheme is presented in figures 2.14-2.18; the unbrand function is presented in figure 2.19; and lump equality is presented in figure 2.20.

Symbol	Name
b	Brand

Chapter 3

Conclusion

Interoperation transparently resolves lazy and eager evaluation strategies by the eager evaluation strategy mirroring the lazy one for reducible expressions inside boundaries in evaluation contexts common to both languages where strictness is incompatible. Forced and unforced evaluation contexts and values comprise a simple framework that implements such a system. This method could be extended to resolve incompatible evaluation contexts for expressions common to any pair of languages.
